Abstract. A *biform theory* is a combination of an axiomatic theory and an algorithmic theory that supports the integration of reasoning and computation. These are ideal for specifying and reasoning about algorithms that manipulate mathematical expressions. However, formalizing biform theories is challenging as it requires the means to express statements about the interplay of what these algorithms do and what their actions mean mathematically. This paper describes a project to develop a methodology for expressing and managing mathematical knowledge as a network of biform theories. It is a subproject of MathScheme, a long-term project at McMaster University to produce a framework for integrating formal deduction and symbolic computation.

We present the *Biform Theories* project, a subproject of MathScheme [6] (a long-term project to produce a framework integrating formal deduction and symbolic computation).

1 Motivation

Type $2 * 3$ into your favourite CAS, press enter, and you'll receive (unsurprisingly) 6. But what if you want to go in the opposite direction? Easy: you ask `ifactors`(6) (or `FactorInteger[6]`)[1] The Maple command `ifactors` returns a 2-element list, with the first element the unit (1 or -1), and the second element a list of pairs (encoded as two-element lists), with (distinct) primes in the first component, and multiplicity in the second. Mathematica's `FactorInteger` is similar, except that it omits the unit (and does not document what happens for negative integers). On top of that, Maple also offers `ifactor` (without the 's') that returns an abomination that displays nicely: a product of a unit and the function with name *the empty string* applied to a prime, raised to its multiplicity. This horrendous hack has the advantage of displaying the result in a way similar to what appears in elementary textbooks.

* This research is supported by NSERC.

[1] depending on whether you prefer Maple or Mathematica, other CASes have similar commands.

This simple example illustrates the difference between a simple computation $(2 * 3)$ and a more complex *symbolic* query, factoring. The reason for using lists-of-lists in both systems is that multiplication and powering are both functions that evaluate immediately. So that factoring 6 cannot just return $2^1 * 3^1$, as that is simply equal to 6. Thus it is inevitable that both systems must *represent* multiplication and powering in some other manner. Because `ifactors` and `FactorInteger` are so old, they are unable to take advantage of newer developments in both systems. Maple calls this feature an *inert form*, while in Mathematica it is a *hold form*, but the idea is the same: representing a computation without actually performing it. Such features are very old: even in the earliest days of Maple, one could do `5 &^256 mod 379` to very compute the answer without ever computing 5^{256} over the integers.

Jacques should complete this section with help from Yasmine with examples.

Computer algebra and theorem proving systems manipulate syntactic representation of mathematical knowledge. However, their way of manipulating them is very different from each other. To illustrate the difference, let's consider the example of factoring polynomials, Given a polynomial p in extended canonical form, $\Sigma_{i=0}^{n} a_i x^i$, factorize it into the product of irreducible polynomials (polynomials that cannot be further factorized) [24].

A theorem proving system (TPS) will use an axiomatic theory to describe this problem. It defines constants representing the language of polynomials and axioms describing their properties. Since polynomials are rings, the axiomatic theory would be similar to the theory of rings with additional axioms representing the different forms that a polynomial can take. The additional axioms include:

- An axiom describing a polynomial in extended canonical form
- An axiom describing what an irreducible polynomial is
- An axioms describing the result of the factorization.

Is this accurate?

The axiomatic theory gives the tools to describe how a what factoring of a polynomial is, but is not capable of describing procedures to compute it. . On the other hand, a computer algebra system (CAS) would use an algebraic theory to represent factorization of polynomials. It describes procedures to calculate the factorization and produce results. Yet, there is no guarantee the results produced are correct. The algorithmic approach is not concerned with specifying the procedures described. Neither representations is capable of producing results that are formally specified.

We used factoring polynomials as an example, but all syntax-based mathematical algorithms (SBMAs) suffer from the same problem. SBMAs are algorithms that produces results by manipulating the syntax of the input. Examples of SBMAs include factoring polynomials, manipulating matrices, computing derivatives and others. They are frequently used in mathematics, that it makes sense to consider reasoning about the behavior of their implementations are crucial task. To be able to perform this reasoning, we need a way to connect a piece of code to its value. In other words, we need to be able to connect syntax and semantics. Biform theories make this possible.

A biform theory is defined as a tuple (L, Π, Γ) where

- L defines constants describing the language of polynomials
- Π defines the algorithms (transformers) that manipulate the syntax of the polynomial to perform different operations - as in the algorithmic theory.
- Γ is a set of axioms. We differentiate between two types of axioms. Some axioms describe the behavior of the constants of the language - as in axiomatic theory. Other axioms, called the meaning formula, which describes the behavior of the transformer by describing how the mathematical meaning of the output expression relates to that of the input expression.

Biform theories enable the specification of algorithms (transformers) via meaning formulas using quotation and evaluation. Consider the example of factoring polynomials. A meaning formula for factorization would subsume the formula

$$[\![\ulcorner x^2 - 1 \urcorner]\!] \equiv [\![\ulcorner (x-1)(x+1) \urcorner]\!]$$

which cannot be expressed without a mean to talk about the semantics of the syntactic representation of the mathematical value.

After presenting a piece of mathematical knowledge, there is a need to connect it to other existing pieces. We believe the best way to do that is by presenting mathematical knowledge as a biform theory graph. For example, we know that polynomials are rings. Therefore, the biform theory of polynomials should be an extension of the biform theory of rings. Adding a new operation to manipulate polynomials boils down to extending the theory of polynomials with the new operation. This way, modularity is forced as well as leveraging the information presented by adding the theory morphisms that enable transportation of results among the graph nodes (the biform theories).

More about theory graph, eg: talk about the little theories approach.

2 Background Ideas

A *transformer* is an algorithm that implements a function $\mathcal{E}^n \to \mathcal{E}$ where $\mathcal{E}$ is a set of expressions. Transformers can manipulate expressions in various ways. Simple transformers, for example, build bigger expressions from pieces, select components of expressions, or check whether a given expression satisfies some syntactic property. More sophisticated transformers manipulate expressions in mathematically meaningful ways. We call these kinds of transformers *syntax-based mathematical algorithms (SBMAs)* [11]. Examples include algorithms that apply arithmetic operations to numerals, factor polynomials, transpose matrices, and symbolically differentiate expressions with variables. The *computational behavior* of a transformer is the relationship between its input and output expressions. When the transformer is an SBMA, its *mathematical meaning* is the relationship between the mathematical meanings of its input and output expressions.

A *biform theory* T is a triple (L, Π, Γ) where L is a language of some underlying logic, Π is a set of transformers that implement functions on expressions

of L, and Γ is a set of formulas of L [3,9,16]. L includes, for each transformer $\pi \in \Pi$, a name for the function implemented by π. The members of Γ are the *axioms* of T. They specify the meaning of the nonlogical symbols in L including the names of the transformers of T. In particular, Γ may contain specifications of the computational behavior of the transformers in Π and of the mathematical meaning of the SBMAs in Π. We say T is an *axiomatic theory* if Π is empty and an *algorithmic theory* if Γ is empty.

Formalizing a biform theory in the underlying logic requires an infrastructure for reasoning about the expressions manipulated by the transformers as syntactic entities. The infrastructure provides a basis for *metareasoning with reflection* [12]. There are two main approaches for obtaining this infrastructure [11]. The *local approach* is to produce a deep embedding of a sublanguage L' of L that include all the expressions manipulated by the transformers of Π. The *global approach* is to replace the underlying logic of L with a logic such as [12] that has an inductive type of *syntactic values* that represent the expressions in L and global quotation and evaluation operators.

A complex body of mathematical knowledge can be represented in accordance with the *little theories method* [15] as a *theory graph* [20] consisting of axiomatic theories as nodes and theory morphisms as directed edges. A *theory morphism* is a meaning-preserving mapping from the formulas of one axiomatic theory to the formulas of another. The theories — may have different underlying logics — serve as abstract mathematical models and the morphisms serve as information conduits that enable theory components such as definitions and theorems to be transported from one theory to another [2]. A theory graph enables mathematical knowledge to be formalized in the most convenient underlying logic at the most convenient level of abstraction using the most convenient vocabulary. The connections made by the theory morphisms in a theory graph then provide the means to find this knowledge and apply it in other contexts.

A *biform theory graph* is a theory graph whose nodes are biform theories. Having the same benefits as theory graphs of axiomatic theories, biform theory graphs are well suited for representing mathematical knowledge that is expressed both axiomatically and algorithmically.

3 Project Objectives

The general objective of the Biform Theories project is:

> **GenObj.** Develop a methodology for expressing and managing mathematical knowledge as a biform theory graph.

Our strategy for achieving this general objective is to pursue the following specific objectives:

> **SpecOBj 1.** Design a logic Log that is version of simple type theory [10] with an inductive type of syntactic values, a global quotation operator, and a global evaluation operator. In addition to a syntax and semantics, define a

proof system for Log and a notion of a theory morphism from one axiomatic theory of Log to another. Demonstrate that SBMAs can be defined in Log and that their mathematical meanings can be stated and proved in using Log's proof system.

SpecOBj 2. Produce an implementation Impl of Log. Demonstrate that SBMAs can be defined in Impl and that their mathematical meanings can be stated and proved in Impl.

SpecOBj 3. Enable biform theories to be defined in Impl. Introduce a mechanism for applying transformers defined outside of Impl to expressions of Log.

SpecOBj 4. Enable theory graphs of biform theories to be defined in Impl. Introduce mechanisms for transporting definitions, theorems, and transformers from a biform theory T to an instance T' of T via a theory morphism from T to T'.

SpecOBj 5. Design and implement in Impl a scheme for defining generic transformers in a theory graph T that can be specialized, when transported to an instance T' of T, using the properties exhibited in T'.

4 Work Plan Status

The work plan for the project is to achieve the five specific objectives described above more or less in the order of their presentation. This section describes the parts of the work plan that have been completed as well as the parts that remain to be done.

SpecObj 1: Logic with Quotation and Evaluation

This objective has been largely been achieved. We have developed CTT_{qe} [14], a version of Church's type theory [7] with global quotation and evaluation operators. (Church's type theory is a popular form of simple type theory with lambda notation.) The syntax of CTT_{qe} has the machinery of $\mathcal{Q}_0$ [1], Andrews' version of Church's type theory plus an inductive type ϵ of syntactic values, a partial quotation operator, and a typed evaluation operator. The semantics of CTT_{qe} is based on Henkin-style general models [19]. The proof system for CTT_{qe} is an extension of the proof system for $\mathcal{Q}_0$.

We show in [14] that CTT_{qe} is suitable for defining SBMAs and stating and proving their mathematical meanings. In particular, we prove within the proof system for CTT_{qe} the mathematical meaning of an symbolic differentiation algorithm for polynomials.

We have also defined CTT_{uqe} [13], a variant of CTT_{qe} in which undefinedness is incorporated in CTT_{qe} according to the traditional approach to undefinedness [8]. Better suited than CTT_{qe} as a logic for interconnecting axiomatic theories, we have defined in CTT_{uqe} a notion of a theory morphism [13].

SpecObj 2: Implementation of the Logic

We have produced an implementation of CTT_{qe} called HOL Light QE [5] by modifying HOL Light [18], a simple implementation of the HOL proof assistant [17]. HOL Light QE provides a built-in global infrastructure for metareasoning with reflection. Over the next couple years we plan to test this infrastructure by formalizing a variety of SBMAs in HOL Light QE.

SpecObj 3: Biform Theories

No work on this objective has been done, but we expect it will be a straightforward task to implement biform theories and the application of external transformer in HOL Light QE.

SpecObj 4: Biform Theory Graphs

We proposed in [4] a biform theory graph test case consisting of eight biform theories encoding natural number arithmetic. We produced partial formalizations of this test case [4] in CTT_{uqe} [13] using the global approach for metareasoning with reflection and in Agda [22,23] using the local approach. After we have finished with SpecObj 2 and SpecObj 3, we intend to formalize this test case in HOL Light QE.

SpecObj 5: Specializable Transformers

Jacques should complete this subsection. Please reference Pouya's thesis [21].
